(A)

In single perceptron

the dataset is distributed across a coordinate system, and the perceptron's task is finding a straight line that devides the dataset into two parts, such that the class distributions lie on the opposite sides of the line.

the function that split dataset is: $0 = w_1 x + w_2 y + b$

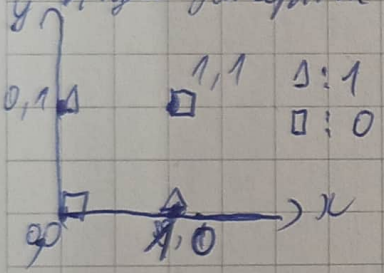

to find the optimal line, we need change value of w_1, w_2 and b.

if change b, the line will slide to the other place

if change x and y the line will rotate.

(B)

Single perceptron can fit with XOR problem because:

this chart describe the value of XOR and we can see clearly that not exist any line that can split 2 class value into two side.

(C)

chain rule in MLP mean the output of the previous layer beam the input of the next layers.

Backpropagation is the process where the model propagates error signals from the output back to the input in order to adjust weights that contributed to the errors.

Just write it
